## Abstract

We propose a new biological framework, *spatial networks of hybrid input/output automata* (SNHIOA), for the efficient modeling and simulation of excitable-cell tissue. Within this framework, we view an excitable tissue as a network of interacting cells disposed according to a 2D spatial lattice, with the electrical behavior of a single cell modeled as a hybrid input/output automaton. To capture the phenomenon that the strength of communication between automata depends on their relative positions within the lattice, we introduce a new, *weighted parallel composition operator* to specify the influence of one automata over another. The purpose of the SNHIOA model is to efficiently capture the spatiotemporal behavior of wave propagation in 2D excitable media. To validate this claim, we show how SNHIOA can be used to model and capture different spatiotemporal behavior of wave propagation in 2D isotropic cardiac tissue, including normal planar wave propagation, spiral creation, the breakup of spirals into more complex (potentially lethal) spatiotemporal patterns, and the recovery of the tissue to the rest via defibrillation.

*Keywords:* Computational Systems Biology, Spatial Networks of Hybrid I/O Automata, excitable cell, excitable tissue

# 1 Introduction

Systems biology is a multidisciplinary field whose goal is to provide a systems-level understanding of biological phenomena by uncovering their structure, dynamics and control methods [19]. A main focus of systems biology is to devise mathematical or formal models that capture significant aspects of in vitro or in vivo experimental data, while remaining amenable to both quantitative and qualitative analysis. Currently, the most popular modeling approach is to use complex systems of nonlinear differential equations, describing in great detail the underlying biological phenomena. Equation-based models, however, are not particularly amenable to formal analysis, and impose high computational demands on simulation, especially in large-scale 2D and 3D networks. Simulation at the organ or even the cell level is thus rendered impractical.

Considering this state of affairs, systems biology could greatly benefit from the development of techniques that given a system of nonlinear differential equation, (semi-automatically) constructs a more abstract model that preserves the properties of interest. One promising approach is based on the use of Hybrid Automata [16,22] as a modeling formalism for complex biological processes. Hybrid Automata (HA) are an extension of finite automata that allows one to associate a continuous behavior with each state. They have been used as mathematical models for a variety of embedded systems, including automated highway systems [10], air traffic management [20] and real-time circuits [1].

More recently, HA have been used to model the behavior of biological systems [2,3,13,23]. In particular, Ye et al. [23] demonstrated the feasibility of using *cycle linear hybrid automata* (CLHA) to model the behavior of several representative excitable cells, basing their derivation on the biological interpretation of these cells' action potential. Note that the focus of this work is on using HA to model the behavior of a single cell.

To model excitable tissue, one should take into account the behavior of a network of spatially distributed components (cells), which have the ability to propagate electrical signals without damping. An impulse over a certain threshold initiates a wave of activity moving across the excitable tissue. As each cell undergoes an excursion from its resting potential, it causes its neighbors to move over threshold at a rate determined by the diffusion coefficient (a property of the tissue), the distance from the stimulated cells, and the rate of rise of the excited cell.

In this paper, we introduce *spatial networks of hybrid I/O automata* (SNHIOA), which extend CLHA with the concepts of space and synchronization based on shared variables. Within the SNHIOA framework, we view an excitable tissue as a network of interacting cells disposed according to a 2D spatial lattice, with the electrical behavior of a single cell modeled as a (cycle-linear) hybrid input/output automaton. To capture the phenomenon that the strength of communication between automata depends on their relative positions within the lattice, we introduce a new, *weighted parallel composition operator* to specify the influence of one automata over another.

The purpose of the SNHIOA model is to efficiently capture the spatiotemporal behavior of wave propagation in 2D excitable media. To validate this claim, we show how SNHIOA can be used to model and capture different spatiotemporal be-

havior of wave propagation in 2D isotropic cardiac tissue, including normal planar wave propagation, spiral creation, the breakup of spirals into more complex (potentially lethal) spatiotemporal patterns, and the recovery of the tissue to the rest via defibrillation.

The rest of this paper is organized as follows. Section 2 provides the biological background on excitable cells. Section 3 discusses related work. Section 4 and 5 describe the HA model and its extension with I/O variables as advocated in [22]. Section 6 introduces the concept of a space lattice, while Section 7 extends HIOA with the concept of space. Section 8 provides a model of an isotropic cardiac tissue of neonatal rat using SNHIOA. Section 9 shows the results of the cardiac tissue simulation. Section 10 offers our concluding remarks and directions for future work.

## 2 Biological Background

An excitable cell has the ability to propagate an electrical signal—known at the cellular level as the *Action Potential* (AP)—to surrounding cells. An AP corresponds to a change of potential across the cell membrane, and is caused by the flow of ions between the inside and outside of the cell. The major ion species involved in this process are sodium, potassium and calcium; they flow through multiple voltage-gated ion channels as pore-forming proteins in the cell membrane. Excitation disturbances can occur in the behavior of these ion channels at the cell level, or in the propagation of the electrical waves at the cell-network level.

Generally, an AP is an externally triggered event: a cell fires an action potential as an all-or-nothing response to a supra-threshold stimulus, and each AP follows the same sequence of phases and maintains the same magnitude regardless of the applied stimulus. During an AP, generally no re-excitation can occur. The early portion of an AP is known as “absolute refractory period” due to its non-responsiveness to further stimulation. The “relative refractory period” is the interval immediately following during which an altered secondary excitation event is possible if the stimulation strength or duration is raised. Figure 1 shows the shape of a neuron’s Action Potential. Examples of excitable cells are neurons, cardiac myocytes and skeletal muscle cells.

Despite differences in AP duration, morphology and underlying ion currents, the following major AP phases can be identified across different species of excitable cells: *resting*, *rapid upstroke*, *early repolarization phase*, *plateau* and *late repolarization*, and *final repolarization* (identical to the resting phase due to the cyclic nature of an AP). The resting state features a constant transmembrane potential (difference between the inside and outside potential of the cell) that is about -80 mV for most species of cardiac cells; i.e. the membrane is polarized at rest. During the AP upstroke, the transmembrane potential rapidly changes, from negative to positive; i.e. the membrane depolarizes. This is followed by an early repolarization phase. A slower, plateau phase is present in most mammalian action potentials, during which calcium influx facilitates muscle contraction. After this phase, a faster final repolarization brings the potential back to the resting state. Due to the universal nature of these AP phases among species and regions, as shown in [24], it is possible to use them as a guide in the construction of HA models.

Fig. 1. *Action Potential of a neuron*

Excitable-cell networks are important in the normal functioning and in the pathophysiology of many biological processes. In cardiac cells, on each heart beat, an electrical control signal is generated by the sinoatrial node, the heart’s internal pacemaking region. Electrical waves then travel along a prescribed path, exciting cells in atria and ventricles and assuring synchronous contractions. Of special interest are cardiac arrhythmias: disruptions of the normal excitation process due to faulty processes at the cellular level, single ion-channel level, or at the level of cell-to-cell communication. The clinical manifestation is a rhythm with altered frequency—tachycardia or bradycardia—or the appearance of multiple frequencies—polymorphic Ventricular Tachycardia (VT)—with subsequent deterioration to a chaotic signal—Ventricular Fibrillation (VF). VF [18] is a typically fatal condition in which there is uncoordinated contraction of the cardiac muscle of the ventricles in the heart. As a result, the heart fails to adequately pump blood, and hypoxia may occur.

### 3 Related Work

An excitable tissue is generally modeled in terms of reaction-diffusion systems. Thus, a typical continuous representation would involve partial differential equations (PDEs) for the diffusing species (typically the transmembrane potential), and a system of nonlinear ordinary differential equations describing all other state variable that are normally considered non-diffusing. These may include ion-channel gating variables and ion concentrations. The first mathematical model of ionic processes that underly cell excitation was empirically developed in 1952 by Hodgkin and Huxley (HH) for a squid giant axon [17]. This provided the basis for subsequent models of increasing complexity, using multiple continuous state variables (voltage, ion-channel gates, ion concentrations) to describe APs in different cell types [6,11,21]. Current models of cardiac cells include more than 20 such state vari-

ables and a large number of fitted parameters. Detailed models of cardiac excitation are perceived as over-determined systems and, as such, make both qualitative—i.e. checking general properties—and quantitative analysis—i.e. by simulation—at the organ or even tissue level impractical.

At the opposite end of the spectrum, completely discrete models based on cellular automata (CA) have emerged [8,12]. The first generation of CA models used nearest-neighbor diffusion modeling (Neumann and Moore neighborhoods) and a small number of few discrete states, resulting in unrealistic AP shape and wave propagation. Second-generation CA models [12] focused on correct representation of wavefront curvature effects by employing more complex neighborhood functions, such as Gaussian, circular templates or randomized lattices. Furthermore, the transitions rules for the relaxation states were updated to reflect a higher threshold for excitation and to effectively represent the relative and absolute refractory period. The latest generation is exemplified by Barkley’s model [5], in which a standard finite-difference method is used to calculate the diffusive term, but CA-like rules govern the kinetics of the two model variables, with adjustable thresholds.

Recently, modified CA models have been used to study cardiac excitability and for comparison with experimental data [8,9]. A body of literature provides clear links between the classical continuous PDE representation and the more ad hoc CA-based approach as an alternative description of reaction-diffusion systems. The purely discrete nature of CA presents some difficulties in capturing subtle non-stepwise features of excitation.

## 4 Hybrid Automata

In this section we briefly report some basic definitions—mostly taken from [22]—that are useful to describe the discrete and continuous behavior of a system. For the aims of this paper, we introduce the key notions of variables, static and dynamic types for variables, and trajectories. More details can be found in [22].

We fix a time axis  $\mathbb{T}$  which is the group  $(\mathbb{R}, +)$ , the real numbers with addition;  $\mathbb{T}^{\geq 0}$  is defined to be the set  $\{t \in \mathbb{T} \mid t \geq 0\}$ . If  $K \subseteq \mathbb{T}$  and  $t \in \mathbb{T}$ , we define  $K + t = \{t' + t \mid t' \in K\}$ . Similarly, for a function  $f$  with domain  $K$ , we define  $f + t$  to be the function with domain  $K + t$  and such that  $(f + t)(t') = f(t' - t)$ , for each  $t' \in K + t$ .

**Definition 4.1** (*Variables and types for variables*) Assume a universal set of variables  $V$ . A variable may represent either a location within a state (*internal variable*) or a location where information flows from one component of the system to another (*external variable*). For each  $v \in V$ , we distinguish a (*static*) *type*, which represents the set of values it may take on, and a *dynamic type*, which represents the set of trajectories  $v$  may follow. In more detail: 1) the (*static*) *type* of  $v$ , denoted by  $type(v)$ , is a nonempty set of values; 2) the *dynamic type* of  $v$  is the set of functions from left-closed intervals of  $\mathbb{T}$  to  $type(v)$  satisfying the following properties:

- (*Closure under time shift*) For each  $f \in dtype(v)$  and  $t \in \mathbb{T}$ ,  $f + t \in dtype(v)$ .
- (*Closure under subinterval*) For each  $f \in dtype(v)$  and  $J \subseteq dom(f)$ ,  $f|_J$ , the restriction of  $f$  to the subinterval  $J$ , is in  $dtype(v)$ .

- (*Closure under pasting*) Let  $f_0, f_1, f_2, \dots$  a sequence of functions in  $dtype(v)$  such that, for each  $i \geq 0$ ,  $f_i$  not the final function of sequence implies  $dom(f_i)$  right-closed and  $\max(dom(f_i)) = \min(dom(f_{i+1}))$ . Then, the function  $f$  defined by  $f(t) = f_i(t)$ , where  $i$  is the smallest index such that  $t \in dom(f_i)$ , is in  $dtype(v)$ .

**Definition 4.2** (*Trajectories*) Let  $V$  a set of *variables*. A *valuation*  $\mathbf{v}$  for  $V$  is a function that associate to each  $v \in V$  a value in  $type(v)$ . We write  $val(V)$  to denote the set of all valuations for  $V$ . Let  $J$  a left-closed interval of  $\mathbb{T}$  with left end-point equal to 0. A  $J$ -*trajectory* for  $V$  is a function  $\tau : J \rightarrow val(V)$  such that, for each  $v \in V$ ,  $\tau \downarrow v \in dtype(v)$  (i.e. the projection of  $\tau$  on the variable  $v$  is in the set of the trajectories that  $v$  may follow). A trajectory for  $V$  is a  $J$ -*trajectory*, for any  $J$ . The set of all possible trajectories for  $V$  is denoted by  $trajs(V)$ .

If  $\tau$  is a trajectory, then  $\tau.ltime$ , the *time limit* of  $\tau$ , is the supremum of  $dom(\tau)$ . Moreover we define the first evaluation of  $\tau$ ,  $\tau.fval$ , to be  $\tau(0)$  and, if  $\tau$  is closed (meaning that its domain is a finite closed-interval), we define the last evaluation of  $\tau$  to be  $\tau(\tau.ltime)$ .

**Definition 4.3** A *Hybrid automaton* (HA for short, see [22]) is a tuple  $\mathcal{A} = (W, X, Q, \Theta, E, H, D, \mathcal{T})$  where:

- $W$  is a set of external variables and  $X$  is a set of internal variables; we assume that  $W$  and  $X$  are disjoint from each other and write  $V = W \cup X$ .
- $Q \subseteq val(X)$  is a set of *states* and  $\Theta \subseteq Q$  is a nonempty set of *initial states*.
- $E$  and  $H$  are disjoint sets of external and internal actions, respectively. We write  $A = E \cup H$
- $D \subseteq Q \times A \times Q$  is a set of discrete transitions. We use  $\mathbf{x} \xrightarrow{a}_{\mathcal{A}} \mathbf{x}'$  as a shorthand for  $(\mathbf{x}, a, \mathbf{x}') \in D$ . We say that the action  $a$  is enabled in  $\mathbf{x}$  if there exists an  $\mathbf{x}'$  such that  $\mathbf{x} \xrightarrow{a}_{\mathcal{A}} \mathbf{x}'$ .
- $\mathcal{T}$  is a set of trajectories for  $V$  such that  $\tau(t)[X \in Q$  for every  $\tau \in \mathcal{T}$  and  $t \in dom(\tau)$ . Given a trajectory  $\tau \in \mathcal{T}$  we denote  $\tau.fval[X$  by  $\tau.fstate$  and, if  $\tau$  is closed, we denote  $\tau.lval[X$  by  $\tau.lstate$ .

We require that the set of trajectories  $\mathcal{T}$  satisfies the following axioms:

- T1** (*Prefix Closure*) For every  $\tau \in \mathcal{T}$  and every  $\tau' \leq \tau$ ,  $\tau' \in \mathcal{T}$ .
- T2** (*Suffix Closure*) For every  $\tau \in \mathcal{T}$  and every  $t \in dom(\tau)$ ,  $\tau \supseteq t \in \mathcal{T}$ .
- T3** (*Concatenation Closure*) Let  $\tau_0, \tau_1, \tau_2, \dots$  be a sequence of trajectories in  $\mathcal{T}$  such that for every index  $i$ ,  $\tau_i.lstate = \tau_{i+1}.fstate$ . Then  $\tau_0 \frown \tau_1 \frown \tau_2 \frown \dots \in \mathcal{T}$ .

For our aims it suffices to only consider HA and pre-HIOA (see Definition 5.1) with real-valued variables (i.e. for each  $v \in V$ ,  $type(v) = \mathbb{R}$ ).

**Notation:** Let  $\tau$  be a trajectory over some set of variables  $V$  and  $v \in V$ . As in [22], we sometimes use  $v$  as shorthand for the function  $\tau \downarrow v : dom(\tau)$ . Similarly, we can view any expression  $e$  containing variables from  $V$  as a function with domain  $dom(\tau)$ . These conventions allow us to say that  $\tau$  satisfies the algebraic equation  $v = e$  meaning that  $v(t) = e(t)$ , for every  $t \in dom(\tau)$ . Similarly, if for every  $t \in dom(\tau)$ ,  $v(t) = v(0) + \int_0^t e(t')dt'$ , we can say that  $\tau$  satisfies the algebraic

equation  $\dot{v} = e$ .

**Definition 4.4** (*Weighted Trajectories*) Let  $e$  be an expression containing variables from a universal set of variables  $V$ . Here, we assume  $V$  partitioned into  $n + 1 \geq 2$  disjoint subsets  $V_1, V_2, \dots, V_n, V - Z$ , where  $Z = \bigcup_{i=1}^n V_i$ . For any index  $i \in [1, n]$ , we denote with  $e_i = e[V_i$  the subexpression of  $e$  (if any) containing only variables from  $V_i$ . Moreover, we write  $e[\bar{Z}$  to denote the subexpression of  $e$  (if any) containing only variables from  $V - Z$  and (possibly) constant subterms. Finally, let  $\mathbf{w} = \{w_1, w_2, \dots, w_n\} \subseteq \mathbb{R}$  be a set of real-valued weights, where each  $w_i$  is the weight associated with the variables in  $V_i$ . We define  $(\mathbf{w} \cdot e)[Z$  to be the expression we obtain from  $e$  by replacing each subexpression  $e_i = e[V_i$  with  $w_i \cdot e_i$ . More formally:

(i) if  $e = e[\bar{Z}$  (i.e. if  $e$  does not contain variables from  $Z$ ),

$$(\mathbf{w} \cdot e)[Z = e$$

(ii) if  $e = e_{i_0} \text{op}_0 e_{i_1} \text{op}_1 \dots \text{op}_{m-1} e_{i_m}$ , where  $i_0, i_1, \dots, i_m$  are indexes from  $[1, n]$ ,

$$(\mathbf{w} \cdot e)[Z = (w_{i_0} \cdot e_{i_0}) \text{op}_0 (w_{i_1} \cdot e_{i_1}) \text{op}_1 \dots \text{op}_{m-1} (w_{i_m} \cdot e_{i_m})$$

(iii) if  $e = e_{i_0} \text{op}_0 e_{i_1} \text{op}_1 \dots \text{op}_{m-1} e_{i_m} \text{op}_m e[\bar{Z}$ , where again  $i_0, i_1, \dots, i_m$  are indexes from  $[1, n]$ ,

$$(\mathbf{w} \cdot e)[Z = (w_{i_0} \cdot e_{i_0}) \text{op}_0 (w_{i_1} \cdot e_{i_1}) \text{op}_1 \dots \text{op}_{m-1} (w_{i_m} \cdot e_{i_m}) \text{op}_m e[\bar{Z}$$

Finally, if  $\tau$  is a trajectory over  $V$  satisfying the equation  $v = e$  ( $\dot{v} = e$ ), we define the *weighted trajectory*  $(\mathbf{w} \cdot \tau)[Z$  to be the trajectory over  $V$  that satisfies the algebraic equation  $v = (\mathbf{w} \cdot e)[Z$  ( $\dot{v} = (\mathbf{w} \cdot e)[Z$ , respectively).

## 5 Hybrid Input/Output Automata

**Definition 5.1** A *pre-hybrid I/O automaton* (pre-HIOA for short, see [22]) is a tuple  $\mathcal{A} = (\mathcal{H}, U, Y, I, O)$  where:

- $\mathcal{H} = (W, X, Q, \Theta, E, H, D, T)$  is an hybrid automaton.
- $U$  and  $Y$  partition  $W$  into *input* and *output* variables, respectively. Variables in  $Z = X \cap Y$  are called *locally controlled*. Again, we write  $V = W \cup X$ .
- $I$  and  $O$  partition  $E$  into *input* and *output* actions, respectively. Actions in  $L = H \cap I$  are called *locally controlled*. Again, we write  $A = E \cup H$ .

A *hybrid I/O automaton* (HIOA for short) is a pre-HIOA satisfying the following additional axioms:

- E1** (*Input action enabling*) For every  $x \in Q$  and every  $a \in I$  there exists  $\mathbf{x}'$  such that  $\mathbf{x} \xrightarrow{a} \mathbf{x}'$ .
- E2** (*Input trajectory enabling*) For every  $\mathbf{x} \in Q$  and every  $v \in \text{trajs}(U)$ , there exists  $\tau \in \text{trajs}(V)$  such that  $\tau.fstate = \mathbf{x}$ ,  $\tau \downarrow U \leq v$  and either (1)  $\tau \downarrow U = v$  or (2)  $\tau$  is closed and some  $l \in L$  is enabled in  $\tau.fstate$

In [22], it has been proved that the parallel composition of two HIOA (or pre-HIOA) is guaranteed to be a pre-HIOA, but property **E2** is not necessarily preserved by the parallel composition operator. Again in [22], it has been shown that to ensure the preservation of such a property some “strong compatibility” assumption is needed. For the aims of this paper, it suffices to consider pre-HIOA and composition of pre-HIOA.

### 5.1 Weighted Composition of Hybrid Input/Output Automata

In this subsection, we introduce a new operation of parallel composition for pre-HIOA. Since a typical hybrid system consists of a collection of HIOA located in 2D space, we first extend the binary parallel composition operator defined in [22] in order to describe the behavior of a set  $\{\mathcal{A}_i \mid i \in [1, n]\}$  of HIOA running in parallel. Moreover, since communication between components of such systems also depends on their positions (meaning that flow of information between a given component and its “neighbors” may be somehow influenced by their relative distance), the parallel composition operator  $\parallel_w \mathcal{A}_i$  (Definition 5.2) uses a real-valued, weight function  $w$  to specify the influence of communication between pairs of automata. We say that two pre-HIOA  $\mathcal{A}_1$  and  $\mathcal{A}_2$  are *compatible* if (1)  $H_1 \cap A_2 = H_2 \cap A_1 = \emptyset$ ,  $X_1 \cap V_2 = X_2 \cap V_1 = \emptyset$  (i.e. if  $\mathcal{H}_1$  and  $\mathcal{H}_2$  are compatible) and (2)  $Y_1 \cap Y_2 = O_1 \cap O_2 = \emptyset$ .

**Definition 5.2** (*Weighted Composition of pre-HIOA*) Let  $\{\mathcal{A}_i \mid i \in [1, n]\}$  be a finite set of pairwise compatible pre-HIOA and let  $w : [1, n] \times [1, n] \rightarrow \mathbb{R}$  be a weight function such that (i)  $w(i, i) = 0$  for each  $i \in [1, n]$  and (ii)  $w(i, j) = w(j, i)$  for each  $i, j \in [1, n]$ . In the following, let  $\mathbf{w}_i$  denote the set of weights  $\mathbf{w}_i = \{w(i, j) \mid j \in [1, n]\}$ .

The weighted parallel composition  $\parallel_w \mathcal{A}_i$  is the tuple  $\mathcal{A} = (\mathcal{H}, U, Y, I, O)$  where:

- $Y = \bigcup_{i=1}^n Y_i$ ,  $U = (\bigcup_{i=1}^n U_i) - Y$ ,  $O = \bigcup_{i=1}^n O_i$ ,  $I = (\bigcup_{i=1}^n I_i) - O$
- If, for  $i \in [1, n]$ , the HA  $\mathcal{H}_i = (W_i, X_i, Q_i, \Theta_i, E_i, H_i, D_i, \mathcal{T}_i)$ , then  $\mathcal{H}$  is the tuple  $(W, X, Q, \Theta, E, H, D, \mathcal{T})$  defined as follows:
  - $W = \bigcup_{i=1}^n W_i$  and  $X = \bigcup_{i=1}^n X_i$ ;
  - $Q = \{\mathbf{x} \in \text{val}(X) \mid \text{for each } i \in [1, n], \mathbf{x} \upharpoonright X_i \in Q_i\}$ ;
  - $\Theta = \{\mathbf{x} \in Q \mid \text{for each } i \in [1, n], \mathbf{x} \upharpoonright X_i \in \Theta_i\}$ ;
  - $E = \bigcup_{i=1}^n E_i$  and  $H = \bigcup_{i=1}^n H_i$ ;
  - for each  $\mathbf{x}, \mathbf{x}' \in Q$  and each  $a \in A = E \cup H$ ,  $\mathbf{x} \xrightarrow{a}_{\mathcal{A}} \mathbf{x}'$  iff, for each  $i \in [1, n]$ , either (1)  $a \in A_i$  and  $\mathbf{x} \upharpoonright X_i \xrightarrow{a}_{\mathcal{A}_i} \mathbf{x}' \upharpoonright X_i$  or (2)  $a \notin A_i$  and  $\mathbf{x} \upharpoonright X_i = \mathbf{x}' \upharpoonright X_i$ ;
  - $\mathcal{T} \subseteq \text{val}(V)$  is given by  $\tau \in \mathcal{T}$  iff, for each  $i \in [1, n]$ , there exists  $\tau_i \in \mathcal{T}_i$  such that  $\tau \downarrow V_i = (\mathbf{w}_i \cdot \tau_i) \upharpoonright I_i \cap O \in \mathcal{T}_i$ .

The composed hybrid automaton  $\mathcal{H}$  and its discrete transitions  $\xrightarrow{a}_{\mathcal{A}}$  are built starting from the hybrid automata  $\mathcal{H}_i$  and their discrete transitions  $\xrightarrow{a}_{\mathcal{A}_i}$  exactly as in [22]. On the contrary, w.r.t. to [22], we provide a different rule for building trajectories of the pre-HIOA  $\parallel_w \mathcal{A}_i$ . Intuitively speaking, a trajectory  $\tau \in \mathcal{T}$  is obtained by combining weighted trajectories of its components in a such way that

the value of each variable  $v \in I_i \cap O$  (i.e. an input variable of a given  $\mathcal{A}_i$  that is an output variable of some other component  $\mathcal{A}_j$ ) also depends on the weight  $w(i, j)$  and, hence, on the distance between  $\mathcal{A}_i$  and  $\mathcal{A}_j$ .

## 6 Spatial Lattices in 2D

Each point in a polar coordinate system can be described with the two polar coordinates, the radial coordinate  $r$  and the angular coordinate  $\theta$ . The  $r$  coordinate represents the radial distance from the pole, and the  $\theta$  coordinate represents the counterclockwise angle from the 0 degree ray (sometimes called the polar axis), known as the positive x-axis on the Cartesian coordinate plane.

**Definition 6.1** We define a *generic 2D spatial lattice* as a function  $\gamma(r, n) = S$  such that:

- $\gamma : \mathbb{R}_{>0} \times \mathbb{N} \rightarrow \mathcal{P}(\mathbb{R}_{\geq 0} \times [0, 2\pi))$ .
- $r \in \mathbb{R}_{>0}$  is the minimum distance between a couple of points.
- $n \in \mathbb{N}$  is the dimension of the lattice.
- $S \subseteq \mathbb{R} \times [0, 2\pi)$  is a set of coordinates identified by the lattice in a polar coordinate system.

**Definition 6.2** We define a *square 2D spatial lattice* as a function  $\overset{\square}{\gamma}$  such that:

$$\overset{\square}{\gamma}(r, n) = \begin{cases} \{(0, 0)\} \cup \\ \{(r, \theta_1), (\sqrt{2}r, \theta_2) \mid \theta_1 = k\frac{\pi}{2}, \theta_2 = (2k+1)\frac{\pi}{4} \mid 0 \leq k \leq 3\} & \text{if } n = 1 \\ \overset{\square}{\gamma}(r, n-1) \cup \{(nr, k\frac{\pi}{2}) \mid 0 \leq k \leq 3\} \cup \\ \bigcup_{i=1}^n \{(s, k\frac{\pi}{2} \pm \theta_i) \mid s = r\sqrt{i^2 + n^2} \leq nr, \text{tg}(\theta_i) = \frac{i}{n}, 0 \leq k \leq 3\} & \text{if } n > 1 \end{cases}$$

**Proposition 6.3** The cardinality of  $\overset{\square}{\gamma}(r, n)$  is:

$$|\overset{\square}{\gamma}(r, n)| = 9 + \sum_{k=2}^n 8k = 9 + 4(n^2 + n - 2) = 4n^2 + 4n + 1 = (2n + 1)^2$$

**Definition 6.4** We define a *triangular 2D spatial lattice* as a function  $\overset{\Delta}{\gamma}$  such that:

$$\overset{\Delta}{\gamma}(r, n) = \begin{cases} \{(0, 0)\} \cup \\ \{(r, \theta) \mid \theta = k\frac{\pi}{3}, 1 \leq k \leq 6\} & \text{if } n = 1 \\ \overset{\Delta}{\gamma}(r, n-1) \cup \\ \{(s, \theta) \mid s = r\sqrt{n^2 - ln + l^2}, \theta = l\frac{\pi}{3n} + k\frac{\pi}{3n}, \text{ if } n > 1 \\ 0 \leq l < n, 0 \leq k \leq 5\} \end{cases}$$

Fig. 2. Square 2D Spatial lattice generated by  $\hat{\gamma}(r, 3)$

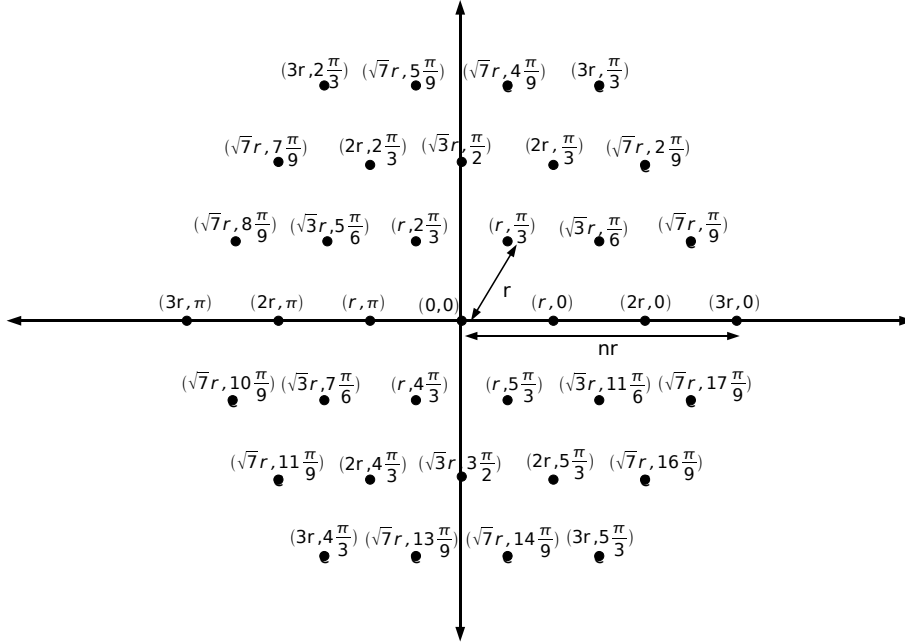

Fig. 3. Triangular 2D Spatial lattice generated by  $\hat{\gamma}(r, 3)$

**Proposition 6.5** The cardinality of  $\hat{\gamma}(r, n)$  is:

$$|\hat{\gamma}(r, n)| = \sum_{k=1}^n 6k + 1 = 6 \sum_{k=1}^n k = 3n^2 + 3n + 1$$

## 7 Spatial Network of Hybrid Input/Output Automata

A spatial network of HIOA is a set of HIOA running in parallel (by taking their weighted composition) and placed in a 2D lattice.

**Definition 7.1** A *spatial network of hybrid input/output automata* is a tuple  $(\mathcal{S}, \gamma, \vec{p}, w)$  where:

- $\mathcal{S}$  is a set  $\{\mathcal{A}_i = (\mathcal{H}_i, U_i, Y_i, I_i, O_i) \mid i \in [1, n]\}$  a set of  $n \geq 2$  mutual pairwise compatible pre-HIOA. This a networks behaves as  $\parallel_w \mathcal{A}_i$ .
- $\gamma$  is a spatial lattice.
- A set of positions  $\vec{p} = \{p_i \mid i \in [1, n]\}$  in a polar coordinate system; each  $p_i = (s_i, \theta_i) \in \gamma$  that represents the position in a 2D spatial of the automaton  $\mathcal{A}_i$ . Moreover, we assume that there exists  $n_{\max} \in \mathbb{N}_{\geq 0}$  such that  $m = |\gamma(r, n_{\max})|$ .
- $w$  is weight function  $w : [1, n] \times [1, n] \rightarrow \mathbb{R}$  such that (i)  $w(i, i) = 0$  for each  $i \in [1, n]$ , (ii)  $w(i, j) = w(j, i)$  for each  $i, j \in [1, n]$ . We can model the fact that  $\mathcal{A}_i$  and  $\mathcal{A}_j$  are too far to influence each other by setting  $w(i, j) = w(j, i) = 0$ .

## 8 Modeling Cardiac Tissue with SNHIOA

In this section we provide a model, using SNHIOA, of a cardiac tissue behavior assuming for ease an isotropic arrangements of the cells: this means that the diffusion of electrical signal is uniform in all directions. In this model each single hybrid automaton represents the behavior of the AP of a single cell. A Triangular lattice has been chosen to mimic the isotropic arrangements. Input/output variables permit the exchange of values between automata. A distance-based weight function mediates this interaction.

**Definition 8.1** Let  $r$  be the minimal distance between a pair of cells,  $n$  the lattice dimension and  $D$  the diffusion constant. We can define an isotropic cardiac tissue, using SNHIOA, as a set of cells (myocytes) arranged in a triangular lattice  $\overset{\Delta}{\gamma}$ . Cells interact through I/O variables mediated by an exponential distance-based function  $w_{d_{\max}}$ , which assigns a non-zero weight to each pair of cells within distance  $d_{\max}$  of each other:

$$Tissue = (Cells, \overset{\Delta}{\gamma}(r, n), \vec{p}, w_{d_{\max}})$$

where:

- $Cells = \{Cell_i = (\mathcal{AP}_i, U_i, Y_i, I_i, O_i) \mid i \in [1, |\overset{\Delta}{\gamma}(r, n)|]\}$
- $w_{d_{\max}}(i, j) = \begin{cases} e^{-\frac{d(p_i, p_j)^2}{d_{\max}} + d_{\max}} & \text{if } i \neq j \wedge d(p_i, p_j) \leq d_{\max} \\ 0 & \text{if } i = j \vee d(p_i, p_j) > d_{\max} \end{cases}$
- $d : \vec{p} \times \vec{p} \rightarrow \mathbb{R}, d(p_i, p_j) = \sqrt{(s_i \cos \theta_i - s_j \cos \theta_j)^2 + (s_i \sin \theta_i - s_j \sin \theta_j)^2}$
- $I_i = \{\overline{stimulated}_i, \underline{stimulated}_i\}$
- $O_i = \emptyset$

- $U_i = \{stimulus_i^{in}\} \cup \{(voltage_k^{out}) | k \in [1, |\hat{\gamma}(r, n)|], k \neq i\}$
- $Y_i = \{voltage_i^{out}\}$

$\mathcal{AP}_i = (W_i, X_i, Q_i, \Theta_i, E_i, H_i, D_i, \mathcal{T}_i)$  is the HA modeling the AP of a single cell such that:

- $W_i = U_i \cup Y_i$ ,
- $X_i = \{v_x, v_y, v_z, \beta_x, \beta_y, \beta_z, d_x, c_x, v, \mu\}$ ,
- $Q_i$  is a subset of valuations of  $V_i = W_i \cup X_i$ ,
- $E_i = I_i \cup O_i$
- $H_i = \{upstroke, plateau, resting\}$
- $\Theta_i$  consists of one valuation which assigns 0 to  $v_x, v_y, v_z$ , the resting potential constant (-80 mV for cardiac cell) to  $v$ ,  $\alpha_x^1$  to  $\beta_x$ ,  $\alpha_y^1$  to  $\beta_y$ ,  $\alpha_z^1$  to  $\beta_z$ , 1 to  $c_x$  and 0 to  $d_x$ .
- $D_i = \{x \xrightarrow{stimulated_i}_{\mathcal{AP}_i} x', x \xrightarrow{\overline{stimulated_i}}_{\mathcal{AP}_i} x', x \xrightarrow{upstroke}_{\mathcal{AP}_i} x', x \xrightarrow{plateau}_{\mathcal{AP}_i} x', x \xrightarrow{resting}_{\mathcal{AP}_i} x'\}$  such that  $x, x' \in X_i$  and:  
 $x \xrightarrow{stimulated_i}_{\mathcal{AP}_i} x'$  performs the following updates <sup>7</sup>:

$$v' = v, \mu = v'/V_R, d_x = 1, \beta_x = 0 \quad (1)$$

$x \xrightarrow{\overline{stimulated_i}}_{\mathcal{AP}_i} x'$  performs the following updates:

$$d_x = 0, \beta_x = \alpha_x^1 f(\mu) \text{ if } v < g(V_T) \quad (2)$$

$x \xrightarrow{upstroke}_{\mathcal{AP}_i} x'$  performs the following updates:

$$c_x = 0, d_x = 0, \beta_x = \alpha_x^2, \beta_y = \alpha_y^2, \beta_z = \alpha_z^2 \text{ if } v \geq g(V_T) \quad (3)$$

$x \xrightarrow{plateau}_{\mathcal{AP}_i} x'$  performs the following updates:

$$c_x = 0, d_x = 0, \beta_x = \alpha_x^3, \beta_y = \alpha_y^3, \beta_z = \alpha_z^3 \text{ if } v \geq h(V_O) \quad (4)$$

$x \xrightarrow{resting}_{\mathcal{AP}_i} x'$  performs the following updates:

$$c_x = 1, d_x = 0, \beta_x = \alpha_x^1 f(\mu), \beta_y = \alpha_y^1, \beta_z = \alpha_z^1 \text{ if } v \leq V_R \quad (5)$$

where  $f(\mu) = 1 + 2\mu$ ,  $g(V_T) = V_T \cdot (1 + 1.45\sqrt{\mu})$ ,  $h(V_O) = V_O - 40\sqrt{\mu}$

- Set  $\mathcal{T}_i$  consists of all trajectories that satisfy:

$$\dot{v}_x = \beta_x v_x + c_x \frac{D}{r^2} \left( \sum_{k=1, k \neq i}^{|\hat{\gamma}(r, n)|} voltage_k^{out} - v_x \sum_{j=1}^{|\hat{\gamma}(r, n)|} w_{d_{max}}(i, j) \right) + d_x stimulus_i^{in} \quad (6)$$

$$\dot{v}_y = \beta_y v_y \quad (7)$$

<sup>7</sup> Here we use the standard convention that  $v$  denotes the value of the variable in the start state of a discrete transition, and  $v'$  denotes the value in the end state.

$V_R$	$V_T$	$V_O$	$\alpha_x^1$	$\alpha_y^1$	$\alpha_z^1$	$\alpha_x^2$	$\alpha_y^2$	$\alpha_z^2$	$\alpha_x^3$	$\alpha_y^3$	$\alpha_z^3$

$$v = v_x - v_y + v_z \quad (9)$$

### 8.1 Instantiating the cardiac tissue model

In this subsection, we instantiate the cardiac-tissue model of Definition 8.1 to the neonatal rat (NNR) AP. We refer the reader to [24] for the details of the NNR CLHA model. Figure 4 shows the AP waveform for a single NNR cell. All parameters used are reported in Table 1 and are obtained using curve-fitting techniques. The HIOA model chosen performs five actions: *stimulated<sub>i</sub>*, *stimulated<sub>i</sub>*, *upstroke*, *plateau*, *resting*, which have the following biological explanations. Initially, the cell is in the resting state. When (externally) stimulated with an action *stimulated<sub>i</sub>* the cell becomes stimulated and updates its voltage adding the current stimulus according to the Equations 1, 6.

Upon termination of the stimulation, via action *stimulated<sub>i</sub>*, with a sub-threshold voltage ( $v < g(V_T)$ ), the cell performs the variables updates according to Equation 2 and returns back to resting state without firing AP. If the stimulus is supra-threshold, i.e., ( $v \geq g(V_T)$ ) holds, the excited cell will generate an action potential by progressing to the upstroke state and performing an *upstroke* action and variables updates according to the Equation 3. This transition could be happen also when the cell is in resting and the sum of the contribute of voltage of its neighbors is supra-threshold. During the upstroke the cell enter in the “absolute refractory period”, so  $d_x$  and  $c_x$  are setting to 0, avoiding any further stimulation. When the voltage reaches an overshoot voltage ( $v \geq h(V_O)$ ) the cell starts the repolarization and performs a *plateau* action and variables updates according to the Equation 4. Then the recovery course of the cell follows the transitions to resting state with an action *resting* and performs variables updates according to the Equation 5 when  $v \leq V_R$ .

## 9 Simulation Results

We have developed CellExcite [7], a simulation environment for excitable-cell networks<sup>8</sup>. CellExcite allows the user to sketch a tissue of excitable cells, plan the stimuli to be applied during simulation, and customize the arrangement of the cells selecting the appropriate lattice. CellExcite adopts SNHIOA as the computational model in order to efficiently capture both discrete and continuous excitable-cell behavior. Figure 5 shows the simulation results of a cardiac tissue of 400x400 cells

<sup>8</sup> The simulator is available at <http://www.cs.sunysb.edu/~eha/download.htm>

Fig. 4. Hybrid I/O Automata representing the AP of a neonatal rat cardiac cell

of a neonatal rat, stimulated three times during the simulation in different regions. The results of this simulation demonstrate the feasibility of SNHIOA to capture and mimic different spatiotemporal behavior of a wave propagation in 2D isotropic cardiac tissue such as the normal propagation of a wave along the tissue (1-150 ms); the creation of dangerous spirals (200-250 ms); the break-up of such spirals into more complex spatiotemporal patterns, meaning the transition to ventricular fibrillation, a lethal type of arrhythmia (250-400 ms); the recovery of the tissue to the rest with the destruction of all waves through an electrical shock, i.e. defibrillation (400-500 ms). Figure 6 shows the difference in wave propagation using a square lattice (see the squarish wave) and using a triangular lattice (see the rounder wave). The triangular lattice was found very suitable to represent the isotropic behavior of an excitable tissue, but other lattices could also be designed to customize the specific cells disposition.

## 10 Conclusions

In this paper we propose a new biological modeling framework based on Hybrid I/O Automata, but extended with the concept of space. This approach was found

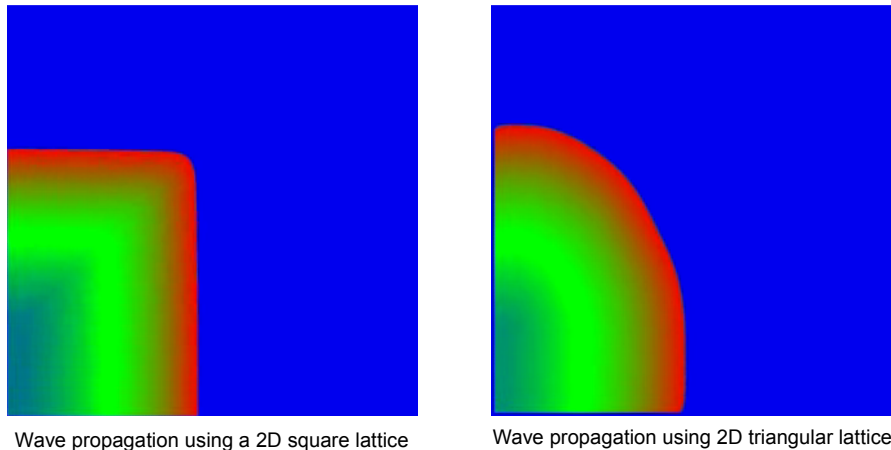

Fig. 6. *Example of wave propagation using square or triangular lattices*

very suitable to better model the spatiotemporal behavior of electrical waves in a 2D cardiac tissue. Our approach naturally evolved as an attempt to combine the benefits of purely continuous PDE methods and computationally efficient CA methods. Previous works [24,25] derived a cycle-linear hybrid automata (CLHA) for several representative excitable cells that approximates with reasonable accuracy their electrical properties. This derivation was made firstly manually [24,25] and then automatically [14] by learning the biological interpretation of their AP.

The term cycle was used to highlight their cyclic structure and the fact, while in each cycle they exhibit linear dynamics, the coefficients of the corresponding linear equations and mode-transition guards may vary in interesting ways from cycle to cycle. The simulation of excitable cells using CLHA models exhibits [24] a nearly eight-fold speed-up in a simulation of 400 by 400 cell network.

Furthermore models based on HA are amenable to formal analysis. Symbolic reachability analysis is a well-established technique in the model checking of linear hybrid systems and are now supported by several tools such as  $d/dt$  [4] and HyTech [15]. We are interested to extend these technique from linear to cycle linear hybrid automata. The study of spatial properties of hybrid automata networks is relative new. Following this direction the work in [13] performed automatic reachability analysis on a HA model for the Delta-Notch signaling network.

In our case study, spatial and temporal properties could be i.e. the spiral detection, the presence or absence—a safety property—of a fatal arrhythmia as fibrillation. Predicting spirals in the pure continuous models is more complicated than use a discrete structure given by the distribution of modes in a SNHIOA. To achieve this goal, we are investigating some model analysis techniques that help us to prevent the state-explosion problem during the model checking but able to capture the spatial properties of interest.
