# Reading the Quotes

---

**Bid and Ask** are what the **market maker** is willing to buy and sell at now. The **Last** sales price is usually between them.

**Volume** is the number of transactions in the option that day.

**Open interest** counts the number of contracts that have been issued to date which have not yet been offset/closed out.

Option prices decrease (increase) with respect to strike price for calls (puts).

# Factors Affecting Option Prices

---

1. The current stock price  $S_0$ .
2. The option strike price  $K$ .
3. The time to expiration  $T$ .
4. The volatility of the stock price  $\sigma$ .
5. The risk-free interest rate  $r$ .
6. The value of dividends expected during the life of the option.

# Impact on Option Prices

---

Suppose each relevant factor increased in isolation. How does that impact the value of an *American* option?

variable	call	put
stock price	+	-
strike price	-	+
expiration date	+	+
volatility	+	+
risk-free rate	+	-
dividends	-	+

## Impact of Rate Changes?

---

The confusing one is the impact of increasing the risk-free rate. If interest increases *independently* of stock price, the present cost (value) of my call purchase (put sale) in the future decreases – good for call, bad for put.

In practice, when interest rates go up usually stock prices down, so a rate increase is bad for a call and good for a put.

The only change with European option prices are that there is no certain relationship with expiration date – for example, increasing  $T$  might cover an extra dividend payment.

# Upper/Lower Bounds on European Option Prices

---

Let  $p$  and  $c$  be the value of European put and call options. We assume no stocks pay dividends.

Since an option to buy a share of stock at any positive price cannot be worth more than the value of the share, so  $c \leq S_0$ .

Since an option to sell a share of stock at the strike price cannot be worth more than the strike price, so  $p \leq K$ .

Since the European option is worth at most  $K$  at maturity, it cannot be worth more than the discounted value of this amount, so  $p \leq Ke^{-rT}$ .

## Better Bounds by Arbitrage Arguments

---

Portfolio  $A$  consists of a European call option for one share at  $K$  plus  $Ke^{-rT}$  worth of cash to execute it at time  $T$ .

At time  $T$ , this is worth  $S_T$  if  $S_T > K$ , or  $K$  if  $K > S_T$  and we don't buy the option, or in other words  $\max(S_T, K)$ .

Portfolio  $B$  consists of one share, and will be worth  $S_T$  at time  $T$ .

That  $A$  is worth more than  $B$  at time  $T$ , implies  $A$  is worth more than  $B$  now since otherwise an arbitrage possibility exists.

Thus  $c + Ke^{-rT} \geq S_0$ . Since no option can have negative value,

$$c \geq \max(S_0 - Ke^{-rT}, 0)$$

## Lower Bound on Puts

---

A similar argument for puts shows that

$$p \geq \max(Ke^{-rT} - S_0, 0)$$

Portfolio  $A$  consists of a European put option for one share at  $K$  at time  $T$  plus one share.

At time  $T$ , this is worth  $S_T$  if  $S_T > K$ , or  $K$  if  $K > S_T$  and we don't buy the option, or in other words  $\max(S_T, K)$ .

Portfolio  $B$  consists of  $Ke^{-rT}$  worth of cash

That  $A$  is worth more than  $B$  at time  $T$ , implies  $A$  is worth more than  $B$  now since otherwise an arbitrage possibility exists.

Thus  $p + S_0 \geq Ke^{-rT}$ .

# Put-Call Parity

---

In fact, there is a tight *put-call parity* relationship between the value of a European put and call. Consider the following portfolios:

Portfolio *A* consists of a European call option for one share plus  $Ke^{-rT}$  worth of cash to execute it at time  $T$ , worth  $\max(S_T, K)$  at time  $T$  by our previous arguments.

Portfolio *C* consists of a European put option plus one share of stock, also worth  $\max(S_T, K)$  at time  $T$ .

Since they have equal value then they must have equal value now, so

$$c + Ke^{-rT} = p + S_0$$

## What About American Options?

---

Similar but weaker bounds hold for American options

$$S_0 - K \leq C - P \leq S_0 - Ke^{rT}$$

The gap here is associated with the observation that one can execute an American option immediately, but the holder of a European option cannot cash in until time  $T$ , when it will be discounted.

Empirical results basically support the bound on over reasonable time scales to the resolution of transaction costs.

## Another View of Put-Call Parity

---

Suppose I buy a call option **and** sell a put option, both at strike price  $K$  and expiration time  $T$ .

The sum of these two payoff functions is linear, just like owning a share! The curve is shifted so profit is zero at  $K$ , however.

The payoff at  $T$  is  $S_T - K$ . Discounting this to the present gives

$$c - p = S_0 - Ke^{-rT}$$

or

$$c + Ke^{-rT} = p + S_0$$
